Communicated by Robert H. Wasserman, March 5, 1993

ABSTRACT The human genome contains large regions that are highly structured. Sequence-related members of multigene families are often found in a clustered organization. Here we describe a previously unrecognized gene cluster composed of genes coding for calcium-binding proteins of the S100 family. The linkage of six S100 genes was established by pulsed-field gel electrophoresis, and a contiguous DNA sequence of 15 kilobases containing the full coding region of four different S100 genes was characterized. This is the tightest mammalian gene cluster discovered so far to our knowledge. Two additional S100 genes are located within the cluster, both of which exhibit unique structural features when compared with other S100 genes. The product of S100E is cysteine-rich, whereas that of S100D contains a long hydrophobic N-terminal tail. The gene cluster was assigned to chromosome 1q21, one of the bands showing rearrangements in neoplasms at high frequency. The deregulated expression of some S100 genes in the cluster during tumor progression suggests that chromosomal abnormalities may influence the expression of S100 genes in late stages of cancer, particularly in association with the formation of metastases.

The human genome is highly organized. Global variations in G+C-content (1) and gene distribution (2) are found. Several genes are arranged in a closely linked gene order. Two classes of these gene clusters can be distinguished: a first group contains genes that are unrelated in sequence, like the mouse surfeit locus (3) and the *Drosophila* shaker complex (4); and a second group contains members of multigene families, like the α -globin and β -globin gene clusters (5), the histone gene clusters (6), and the homeobox gene clusters (7).

What is the genetic advantage that keeps these genes in a clustered organization? One motive might be the overall regulation of transcripts within gene clusters—for example, by locus control regions (8), by the maintenance of the correct gene order (9), or by the location within chromosomal domains of particular "chromatin flavor" (10). Information about clustered multigene families is rare and restricted to genes that are expressed only in a certain cell type (globin genes, α -amylase genes) and to genes that show a strictly developmental expression pattern (homeobox genes, globin genes).

S100 proteins[¶] are small EF-hand calcium-binding proteins (11) of variable sequence identities (38 to 63%). Each member of this gene family displays a quite different expression pattern in human tissues. Some S100 proteins are associated with tumor development and the metastatic behavior of tumors. S100L is preferentially expressed in normal mammary epithelial cells and not in breast tumor cells (12). Calcyclin (CACY), S100 α , and S100 β , on the other hand, show enhanced expression with tumor progression (11). The expression of CAPL (calcium protein, murine placental homologue) increases with increasing degrees of metastasis in mouse mammary carcinoma and leukemic cells (13).

Indications that S100 genes might form a gene cluster came from their colocalization on human chromosome 1 (12, 14– 16). The S100 gene cluster described in this work contains at least six different S100 genes, including two previously unreported members of this family.^{||} The compact organization of the genes and their diverse expression patterns suggest regulation mechanisms different from other gene clusters. The assignment of this cluster to human chromosome 1q21, a chromosome band often involved in tumorassociated rearrangements, together with their deregulated expression patterns in cancer suggests a participation of some S100 genes in tumor progression.

MATERIALS AND METHODS

Polymerase Chain Reaction (PCR). Total RNA of different human tissues was isolated by the guanidinium isothiocyanate method (17). First-strand cDNA was synthesized by using Superscript (BRL) reverse transcriptase. Boehringer *Taq* DNA polymerase was used for PCR.

Oligonucleotides. The following primers were used in which B = C, G, or T; N = A, C, G, or T; M = A or C; Y = C or T; R = A or G; S = C or G; K = G or T; V = A, C,or G: Cons-I, TBNMYRYSTTCCACTAGTAYTCNGKSM-RVGA (contains recognition sequence for Spe I); Cons-IV, GGAGAGCTCSBTBBSAKNAGYTCYTTSAG (contains recognition sequence for Sst I); RACE-I-O-(T)₁₇, AAGTC-GACATCGATGGATCCTGCAGAAGC(T)17; RACE-0, AAGTCGACATCGATGGATCC; RACE-I, GATG-GATCCTGCAGAAGCTT; RACE-D31, GAGGGTAG-CAAACTGACCCT; RACE-D32, GACCCTGAGTAG-GAAGGAAC; RACE-D51, GATCTCCTGGTCGCTGT-TCT; RACE-D52, TGTCCAGGCTCTTCATCAAG; RACE-E51, CGGGGTCCAGGTGGCCAGCTC; RACE-E52, CTTCTGCAGCAGCTCCTTGAG; S100D-A, GAGTAA-AGTTTCTGGGATTGGG; S100D-B, AAAGAGGGTC-

[¶]To avoid confusion about the different names given to S100 proteins, we will use the nomenclature of the committee of the Tenth International Workshop on Human Gene Mapping (1989). All other names are listed in Table 1.

The sequences reported in this paper have been deposited in the GenBank data base [accession nos. Z18954 (S100D cDNA), Z18948 (S100E cDNA), and Z18949 and Z18950 (S100 gene cluster)].

TGTGAGAGGAGC; S100E-A, GTCTCAGATTGGTAA-ACACCCC; S100E-B, GGCAAGTCCAGATTGAA-AGGGG.

PCR with degenerated primers. Human genomic DNA was isolated from blood lymphocytes (17). PCR was performed in 100- μ l reaction mixtures containing 2 nmol each of the primers Cons-I and Cons-IV, 1 μ g of genomic DNA as template, and 2.5 units of *Taq* DNA polymerase. Cycle steps were as described in Engelkamp *et al.* (18).

3'-Rapid amplification of cDNA (RACE). Amplification of the S100D cDNA 3' end was performed as described by Frohman (19) with the following modifications: total RNA (3 μ g) was reverse-transcribed by using 0.1 nmol of RACE-I-O-(T)₁₇ as primer; cycle steps were 1 min at 95°C, 1 min at 65°C, and 1.5 min at 72°C (30 cycles). The primer pairs used for the first and second round of amplification were: RACE-D31/RACE-O and RACE-D32/RACE-I.

5'-RACE. Amplifications of the S100D and S100E cDNA 5'-ends were performed by the method of Frohman (19). Total RNA (30 μ g) was reverse-transcribed in a total volume of 50 μ l by using 1.0 μ g of random hexamers as primers. After poly(A)-tailing (terminal deoxyribonucleotidyltransferase, BRL), 1/25th of this first-strand cDNA mixture was used as template for amplification. The primer sets used for the first and second round of amplification were: Oligo-I-O-(T)₁₇/ RACE-O/RACE-D51 (S100D) or Oligo-I-O-(T)₁₇/RACE-O/ RACE-E51 (S100E) and RACE-I/RACE-D52 (S100D) or RACE-I/RACE-E52 (S100E). The cycle steps were as follows: 1 min at 95°C, 1 min at 65°C, 1.5 min at 72°C (30 cycles). The first amplification round was preceeded by one cycle at 37°C annealing temperature (1 min at 95°C, 10 min at 37°C, and 60 min at 55°C).

cDNA amplification. Total RNA (3 μ g) was reversetranscribed in a total volume of 20 μ l with 0.1 nmol of oligo(dT)₁₅ as primer. cDNAs of S100E and S100D were amplified at standard conditions (17). Primer sets were: S100E-A/S100E-B and S100D-A/S100D-B.

Isolation of Genomic DNA Containing Phages. Two human genomic libraries (Clontech, nos. HL 1067J and HL 1006D) were screened with $[\alpha^{-32}P]dCTP$ random-primed cDNA probes of CACY, CAPL, and S100D as described by Sambrook *et al.* (17). Sequencing of DNA subcloned into Bluescript SK(+) (Stratagene) followed the Sanger protocol (20), and sequence analysis was performed with the GCG sequence analysis software package of the University of Wisconsin (21).

Pulsed-Field Gel Electrophoresis (PFGE). Human genomic DNA used for mapping was isolated from the human epithelial cell line HEp-2. Logarithmic-phase culture cells were embedded in low-gelling-temperature agarose, processed, and digested as described by Sambrook *et al.* (17). Restriction enzyme-digested DNA was resolved at 14° C and 200 V by contour-clamped homogenous electrophoresis (CHEF system, Bio-Rad) with 60-sec pulses for 15 hr, followed by 90-sec pulses for an additional 9 hr. After electrophoresis, the DNA was transferred to Hybond-N membrane (Amersham) by diffusion blotting and was hybridized (17). Exposure times were 4 and 6 days. Complete removal of the previous probe was checked by exposure for at least 2 days before rehybridization with the next probe.

In situ Hybridization. In situ hybridization on chromosome preparations was carried out as described (22).

RESULTS

S100D and S100E Are Two Previously Unreported S100 Proteins. Initially we attempted to search for new S100 proteins using a degenerated PCR approach. Oligonucleotides were constructed against conservative regions in the first calcium loop of S100 proteins. This sequence region Proc. Natl. Acad. Sci. USA 90 (1993)

contains the noncanonical EF-hand (calcium loop of 14 amino acids), which is specific to S100 proteins and significantly different from the canonical EF-hand (calcium loop of 12 amino acids) (23). In all known S100 genes, the first calcium loop is encoded by a single exon. A low-stringency PCR was performed on human genomic DNA under the same conditions as those used to screen for S100 proteins in human heart RNA (18). After subcloning and sequencing, we identified 23 clones as known human S100 genes (S100 α , nine separate clones; S100 β , 3; CACY, 10; and CAPL, 1). Twelve clones revealed no sequence homology to S100 genes. Four clones, with identical sequence within the amplified region, were homologous to S100 genes but could not be attributed to published S100 sequences. This suggested that we had identified an unrecognized S100 gene, which we designated S100D. The 5' and 3' ends of the expected cDNA were amplified by RACE (19). To verify the linkage of the 5'- and 3'-RACE products, the entire translated part was amplified from human kidney and heart RNA and sequenced.

The complete S100D cDNA (709 base pairs, not shown) contains an unusually long 5' untranslated leader sequence, compared to other S100 cDNAs. In contrast to all other S100 cDNAs, S100D codes for additional 18 amino acids at the N terminus (Fig. 1). Hydrophilicity analysis revealed that this protein domain is highly hydrophobic. No sequence homology between this *N*-terminal sequence and other proteins was found by searching GenBank and Protein Identification Resource data bases. By comparison of the deduced amino acid sequence to other members of the S100 protein family, S100D clearly was identified as an S100 protein (the first calcium loop contains 14 amino acids; Fig. 1). Highest degrees of identities were found to CACY (54%), CAPL (53%), and S100L (52%).

In our sequence analysis of the S100 gene cluster (described below), we discovered genomic subclones coding for a second unreported S100 gene, termed S100E. The 5' end of the cDNA was amplified by RACE, and cDNA clones spanning all three exons and coding for the whole translated part were generated by PCR. Different subcloned PCR products of lung and heart RNA revealed no sequence variation when compared to the genomic DNA. The S100E cDNA (738 base pairs, not shown) contains one long open reading frame with strong sequence homology to the amino acid sequence of S100 proteins and the characteristic calcium loop spanning 14 amino acids. The highest sequence identities of the deduced S100E amino acid sequence were found to CACY, CAPL, and S100D (46%). Different from all other S100 proteins is the high content of cysteines in S100E. Ten of a total of 101 amino acids are cysteine residues. Five of them are located within the terminal 21 amino acids. We found no sequence similarities to metallothioneins or zinc-finger proteins-two protein families with increased cysteine occurrence. Like S100D, S100E is unique in the S100 protein family (Fig. 1).

On Northern blots no transcripts of S100D and S100E were detectable. We therefore applied a quantitative PCR technique to determine the expression patterns. Fragments of S100D, S100E, and human β -actin cDNAs as a control were amplified by PCR using equal amounts of reverse-transcribed RNA as template (results not shown). S100D and S100E both showed a very low general expression in diaphragm, heart muscle, skeletal muscle, stomach, lung, liver, fat tissue, and placenta. In addition, S100D (but not S100E) was also expressed in neuronal tissues. Using various primer sets, in most human tissues S100E was expressed at higher levels than S100D. Compared to other S100 genes, both show, however, low transcription levels. In contrast, CACY and CAPL, both located in the same gene cluster (see below), are clearly detectable on Northern blots and are highly expressed in various human tissues (18).

The Complete Coding Region of Four S100 Genes Is Organized Within 15 kilobases of the Human Genome. In a search of the EMBL DNA data base with the complete cDNA sequence of S100D, we found a 100% identity of the S100D 3' cDNA end (base pairs 494-709) to the promoter region of human CACY (14) (base pairs -1371 to -1175). The most simple explanation of this sequence identity is that in the human genome, the two S100 genes are located directly one after another in a head-to-tail fashion. To prove the direct linkage of S100 genes, we analyzed the gene region surrounding the CACY gene. Two genomic libraries were screened with cDNA probes corresponding to human CAPL, S100D, and CACY. Only phages that hybridized to at least two of the probes were analyzed. Four different, overlapping phages, corresponding to 33 kb of genomic DNA, were mapped by restriction enzyme digestion and Southern hybridization (Fig. 2). In our attempt to map the gene order of the three S100 genes, we found an additional unknown S100 gene localized close to the human CAPL gene. Isolation and characterization of the corresponding complete cDNA, designated S100E, has been described above. The genes of S100E, CAPL, and S100D (except parts of the third S100D intron) were sequenced completely. Since the CACY gene has been published previously (14), this genomic region was only partially sequenced and found to be identical to the

FIG. 1. Amino acid sequence comparison of S100D and S100E with all known S100 proteins. To get a maximum of homology in the alignments, gaps were introduced at those positions where an intron interrupts the first and second EFhand. The positions of the two calcium-binding loops are indicated by black bars. The dendrogram reflects sequence relationship among the different S100 proteins. The position of an allelic sequence variation $(D \rightarrow G)$ found in S100D is indicated by a large black dot. Intron positions are marked by an arrow.

published sequence. The four S100 genes are arranged in a direct head-to-tail order: 5'-S100E-CAPL-S100D-CACY-3' and are transcribed in the same direction (Fig. 2). By partially sequencing the 5' region of S100E and the 3' region of CACY, we obtained no further indications for the localization of other S100 genes in our cloned fragments.

Like other S100 genes studied so far, the genes of CACY (14), S100E, and CAPL (24, 25) are composed of three exons and two introns. In all cases the two EF-hand coding sequences are on separate exons (exons II and III). The first exon is not translated in any one of the S100 genes. The gene structure of S100D is, in contrast, organized into four exons and three introns. The third and the fourth exon, coding for the two EF-hands, correspond to the second and third exon in other S100 genes. Interestingly, exon II of S100D codes for 13 of the additional 18 amino acids that are not present in other S100 proteins. Exon I is not translated into protein sequence.

No direct evidence for gene duplication of parts of this cluster was seen. Intron, intergenic, and noncoding sequences of *S100E*, *CAPL*, *S100D*, and *CACY* show no sequence homologies to each another. Therefore, the division of *S100* genes by gene duplication of an ancestral gene must have occurred early in evolution. Further comparison of the human *CAPL* gene with the corresponding genes of rat

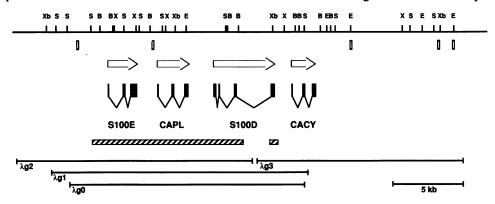

FIG. 2. Organization of the human S100 gene cluster. Restriction enzyme maps in the top line for Bam I (B), EcoRI (E), Sst I (S), Xba I (Xb), and Xho I (X) were deduced by single and double digests of genomic DNA-containing phages ($\lambda g0$ to $\lambda g3$). Below this line, identified Alu family repeats are designated by open boxes. Filled boxes in the center connected by thin lines correspond to exon sequences. The direction of transcription is indicated by open arrows. The regions marked by hatched bars were sequenced completely and submitted to the GenBank data base.

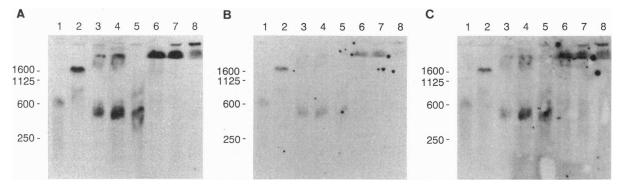

FIG. 3. Autoradiographs of a human PFGE Southern blot sequentially hybridized with S100 α (A), S100L (B), and CAPL (C) sizes are shown in kb. Fragments in lanes: 1, Not I; 2, Sal I; 3, BssHII; 4, BssHII/Nru I; 5, BssHII/Mlu I; 6, Mlu I/Nru I; 7, Mlu I; 8, Nru I.

(24) and mouse (25) revealed a high degree of similarity, even outside the exon sequences (exons: 76–87% identity; introns, 5' and 3' surrounding sequences: 64–85% identity).

The total (G+C) content of the sequenced parts approaches about 56%. This is higher than the average (G+C) content of the human genome. In addition, in all four genes the (G+C) content of the third-codon-position bases is higher than 75%. At least five different *Alu* family repeats are present in the cloned region (Fig. 2). This indicates that the gene cluster might be located within "T-bands" of the chromatin (10). The total gene complex analyzed in this work spans a region of 15 kb (5' end of *S100E* to 3' end of *CACY*) and contains the complete coding sequences for four different genes. As far as we know, this is the tightest human gene cluster reported up to now.

At Least Six S100 Genes Are Linked Within 450 kb of Genomic DNA. The chromosomal colocalization of S100 genes (12, 14-16) on the human chromosome 1 suggests that our cluster is only part of a larger S100 gene cluster. Therefore, we analyzed a more extended gene region by PFGE. Three S100 and a β -actin cDNA probes were successively hybridized: CAPL as a member of the four-gene cluster, S100L (the cDNA was amplified by PCR and corresponds to the sequence of clone CaN19) (12) and S100 α (18). We chose S100L, as this cDNA has the highest homology to the four S100 genes of the cluster, and S100 α as a cDNA with higher sequence divergence. All three S100 cDNA probes revealed an identical hybridization pattern (Fig. 3; β -actin hybridization resulted in a different pattern and is not shown). The smallest fragment that hybridized to the three probes was generated by digestion with BssHII. The length of this fragment was calculated to be about 450 kb.

These results clearly demonstrate the existence of a large S100 gene cluster containing at least six genes (S100E, CAPL, S100D, CACY, S100L, and S100 α) within 450 kb.

Assignment of the S100 Gene Cluster to Human Chromosome 1q21. To precisely localize the S100 gene cluster on chromosome 1, S100D and S100 α (not shown) were mapped by *in situ* hybridization. In 100 metaphase cells analyzed by each probe 16.1% (S100 α) and 18.9% (S100D) of the silver grains were located on chromosome 1. Of these 62.3% (S100 α) and 62.5% (S100D) mapped to the region 1q21. These results allowed us to map S100 α and S100D (together with S100E, CAPL, and CACY) to the 1q21 band of the human genome. They are in agreement with the previous localization of CACY to 1q21-25 (14), CAPL to 1q12-22 (15), and S100 α to chromosome 1 (16).

DISCUSSION

The tight linkage of six S100 genes was established by gene cloning and PFGE. Two unreported S100 genes were identified in this gene cluster. Both exhibit unique features within

the S100 gene family. S100D gene product contains a long hydrophobic N terminus, which may interact with hydrophobic binding partners. Ca[1] (26) and CACY (27), for example, interact with members of the annexin protein family. Alternatively, it may function as a signal peptide for secretion of the protein. Other S100 proteins display extracellular functions (11, 28, 29) but lack signal peptide-like sequences.

S100E has the highest content of cysteines of all calciumbinding proteins. Possibly, cystine bridges are formed that stabilize tertiary structures of S100E and might affect calcium-binding properties. The correct formation of disulfidebridged dimers is thought to be important for the biological activity of S100 proteins (11). The deletion of a cysteine residue in S100 β , for example, leads to a loss of function (29).

The sequenced region of the gene cluster contains four S100 genes in a head-to-tail order (5'-S100E-CAPL-S100D-CACY-3'). Two additional S100 genes $(S100L \text{ and } S100\alpha)$ were linked to the gene cluster by PFGE within a maximal region of 450 kb in the human genome. In addition, the chromosomal colocalization of CAGA and CAGB (15) and the assignment of Ca[1] gene to a syntenic region on mouse chromosome 3 (30), implicates the existence of an even larger gene cluster (15) (Table 1).

Table 1. Chromosomal assignment of S100 genes

		Chrom		
Gene	Synonyms	Human	Mouse	Ref.
S100α		1q21		*
S100β	NEF	21q22	_	31
S100P		_		
CAPL	p9ka, 42A, pEL98, mts1, metastasin, calvasculin, 18A2	1q21	3	* 15
S100L	CaN19	1q21	_	*
CACY	2A9, PRA, CaBP,	1q21	3	*
	5B10, calcyclin			32
S100D		1q21		*
S100E		1q21	—	*
Ca[1]	p11, p10, 42C, calpactin light chain		3	30
S100C	calgizzarin		_	
CaBP9k	ICaBP, Calbindin-D9k	Х	—	33
CAGB	CFAg, MRP14, p14, MAC387, 60B8Ag, L1Ag, MIF, NIF	1q12-21	3	15
CAGA	CFAg, MRP8, p8, MAC387, 60B8Ag, L1Ag, CP-10, MIF, NIF	1q12-21	3	15

Synonyms of S100 proteins used by various authors. *, Results of authors; -, not determined.

This report identifies a gene cluster of calcium-binding proteins. Other EF-hand calcium-binding proteins with strong sequence relations were assigned to different human chromosomes (34). Calmodulin genes (presently three genes are known) are not clustered (35).

The overall expression pattern of the S100 genes within this cluster is not comparable to those of other gene clusters. Most S100 proteins are expressed in more than one tissue. But each S100 protein is restricted to its own specific set of (different) cell types (11). S100 α , for example, is expressed in neurons, heart muscle cells, and slow twitch muscle cells (36), whereas CACY is expressed in fibroblasts and epithelial cells (37). So far we could also not find a temporal correlation. In contrast, all genes of the globin gene clusters are expressed only in one particular cell type, the erythroid cells (5). Furthermore, the expression of globin and homeobox genes is dependent on the gene order within the clusters in either temporal or spatial manner (7, 9). Therefore, we suggest a regulatory mechanism that allows individual and independent expression of each S100 gene in the cluster. The heterogeneity in the S100 promoter regions supports this idea (sequence analysis data of the promoter regions are not shown).

The in situ assignment to chromosome 1q21 and the nucleotide composition of the sequenced region suggests that the gene cluster is located on a chromosomal "T-band." These are highly active, G+C-rich, and Alu-rich chromosomal regions that represent only 15% of all chromosome bands but contain 65% of mapped genes, 60% of cancer-associated breaks, and 42% of x-ray-induced breaks (10). In that respect it is intriguing that in human solid tumors, the single chromosome most frequently involved in structural alterations is chromosome 1 (38). One of the regions affected is 1q21. Chromosome abnormalities around 1q21 were found in breast carcinoma with a frequency of 30% (39, 40), gastric carcinoma (41), and leukemic B-cell clones (42). Furthermore, at least three S100 genes located within the cluster show a deregulated expression in association with tumor progression. CAPL expression is increased in mouse mammary carcinoma or leukemic cells with a higher degree of metastatic potential (13). CACY is expressed at higher levels in cells from patients with acute myeloid leukemia than in normal cells (14). On the contrary, S100L is preferentially expressed in normal mammary epithelial cells but not in breast tumor cells (12). This suggests that chromosomal aberrations may alter the organization of S100 genes during tumor progression. The occurrence of translocations, duplications, or deletions of chromosome segments might lead to a deregulated expression. One example for a gene whose expression is associated with neoplastic transformation is HOX-11. Overexpression of HOX-11 in T-cell acute lymphoblastic leukemia is caused by translocations with breakpoints in the 5' regulatory region of the gene (43).

We are grateful to Dr. P. Deloukas and Dr. A. P. G. M. van Loon (Hoffmann-La Roche, Basel) for providing technical assistance on PFGE, to E. Wey for her help in performing RACE experiments, and to M. Killen and M. Pedrocchi for critical reading of the manuscript. This work was supported by Grants no. 31-30742.91 and no. 32-029975.90 of the Swiss National Science Foundation and by the Helmut Horten Stiftung.
