Key Points:

- Peat soil layer geometry controls spatial pattern and extent of simulated groundwater exfiltration flux

- Landscape slope and porous media hydraulic properties control total groundwater exchange flux magnitude more than peat layer geometry

- Hydrological impact of groundwater drawdown near groundwater-fed peatlands is not captured by monitoring peatland groundwater levels alone

Abstract

Fully-integrated physically-based hydrological modeling is an essential method for increasing hydrological understanding of groundwater-surface water (GW-SW) interactions in peatlands and for predicting anthropogenic impacts on these unique ecosystems. Modeling studies represent peat soil in a simplistic manner, as a homogeneous layer of uniform thickness, but field measurements consistently show pronounced spatial variability in peatlands. This study evaluated uncertainty in groundwater levels and exfiltration fluxes associated with the simplified representation of the peat soil layer. For transferability of the results, impacts of selected topographical and hydrogeological conceptual models on GW-SW exchange fluxes were simulated in a hypothetical hillslope representing a typical aquifer-mire transect. The results showed that peat soil layer geometry defined the simulated spatial GW-SW exchange patterns and groundwater flow paths, whereas total groundwater exfiltration flux to the hillslope and groundwater level in the peatland were only subtly altered by different conceptual peat soil geometry models. GW-SW interactions were further explored using different scenarios and dimensionless parameters for peat hydraulic conductivity and hillslope-peatland system slope. The results indicated that accurate representation of physical peat soil properties and landscape topography is important when the main objective is to model spatial GW-SW exchange. Groundwater level in virtual peatland was not greatly affected by groundwater drawdown in an adjacent aquifer, but the magnitude and spatial distribution of GW-SW interactions were significantly altered. This means that commonly used groundwater depth observations near peat-mineral soil interfaces and within peatlands may not be a suitable indicator for monitoring the hydrological state of groundwater-dependent peatland ecosystems.

1 Introduction

Pristine boreal and subarctic peatlands are highly valued ecosystems due to their unique fauna and the flora and ecosystem services they provide. These peatlands play an important role in global carbon sequestration, storing around one-third of terrestrial carbon (Gorham, 1991; Turunen et al., 2002). Some boreal/subarctic peatlands are sustained by groundwater from glaciofluvial eskers or other glacial soil formations (Isokangas et al., 2017; Nadeau et al., 2015; Rossi et al., 2012; Winter et al., 1998). When groundwater discharges at the surface of a mire (typically named acrotelm), it creates a distinct type of groundwater-surface water (GW-SW) interaction sustaining specific groundwater-dependent flora. Despite groundwater flow can being of the main drivers of biogeochemical processes in peatlands, the role of groundwater in peatland water, carbon and nutrient balances is still poorly understood. Filling this knowledge gap requires a better understanding of the dynamics of GW-SW interactions and ability to quantify them with field methods and numerical modeling.

A variety of field techniques are available for i) studying the GW-SW interface, ii) monitoring GW-SW interactions over different scales, and iii) assisting in classification and delineation of groundwater-dependent peatlands. These techniques, applicable for peatland sites, include conventional direct hydrological measurements (use of piezometers, slug tests, boreholes, etc.) (Johansen et al., 2011; Rossi et al., 2012), thermal imaging and other remote sensing techniques (Bechtold et al., 2018; Briggs et al., 2016; Hare et al., 2015, 2017), geophysical measurements (Lowry et al., 2009; McLachlan et al., 2017), and use of natural tracers, including stable water isotopes (Isokangas et al., 2017; Levy et al., 2014, 2016; Négrel et al., 2010). These methods provide valuable information on the current state of GW-SW connectivity, but are of little use in predicting how the system will react to changing conditions, such as groundwater abstraction, changes in land use, or climate change. Current monitoring technology also has limited capability for quantifying GW-SW interactions at large scales, such as catchment or regional scale. Quantifying GW-SW interactions at larger scales may still be necessary to resolve carbon balance and water management questions.

Numerical modeling provides a unique method to study GW-SW interactions at large scales. In the past, groundwater and surface water hydrology were conceptually differentiated and modeled by separate modeling approaches (Barthel, 2014). However, as groundwater and surface water form a continuum, the need for a holistic hydrological approach is now widely recognized (Barthel & Banzhaf, 2016; Winter et al., 1998). Most recent hydrological modeling applications attempt to include representations of both surface and subsurface domains, but the rigor of physical flow process representation varies between applications. A common approach is to apply so-called 'loosely coupled schemes', in which two or more individual models or model packages are coupled to each other via exchange of results, by using output of one model as input to the other (e.g., Roland Barthel & Banzhaf, 2016). Fully-integrated physically-based models are a step forward, providing a realistic and physically-based framework to simulate exchange fluxes between groundwater aquifers and groundwater-dependent ecosystems. By creating seamless physically-based descriptions of the whole hydrological cycle, including saturated and unsaturated groundwater flow and surface flow, these models solve numerical equations simultaneously and allow for a continuum of different model components.

This continuum permits systematic description of various hydrological responses and enables dynamic changes in groundwater and surface water processes to be studied. The close GW-SW coupling is essential in the case of groundwater-dependent mires, where the water flux through the peat-mineral soil interface provides information on the availability of possibly nutrient- or mineral-rich groundwater, whichis a prerequisite for typical indicator plant species of groundwater-dependent peatlands that have limited ability to take up water from greater

depths (Aldous & Bach, 2014). Although a variety of fully-integrated codes are available, only a few are in common use from which the most popular ones are HydroGeoSphere (Aquanty, 2015), ParFlow (Kollet & Maxwell, 2006) and OpenGeoSys (Kolditz et al., 2012). Fully-integrated codes differ in the formulation of governing equations, the coupling between GW-SW domains, and spatial and numerical discretization (see e.g., Kollet et al., 2017; Maxwell et al., 2014). They have been utilized to model GW-SW interactions over a range of landscapes and climates (Ala-aho et al., 2015; Chow et al., 2018; Glaser et al., 2016; Gleeson & Manning, 2008; Jones et al., 2008), including peatlands (Ala-aho et al., 2017; Hwang et al., 2018; Thompson et al., 2015; Thompson et al., 2017).

However, there is no rigorous framework on how to represent peat soils in fully-integrated GW-SW models. Peat soils have highly heterogeneous properties (Baird et al., 2008; Beckwith et al. 2003; Holden & Burt, 2003; Isokangas et al. 2017; Lewis et al., 2012, Päivänen, 1973; Rosa & Larocque, 2008) and are thus difficult to represent in numerical models. Field studies have shown that factors such as preferential flow paths (Holden & Burt, 2002; Lowry et al., 2009), hydraulic conductivity (Drexler et al., 1999; Hare et al., 2017), and abrupt changes in peat thickness (Hare et al., 2017; Lowry et al., 2009) may affect the location of groundwater discharge. However, most fully-integrated physically-based modeling studies tend to represent the peat domain in a simplified manner, as a constant-depth layer with homogeneous hydraulic properties. An overview of previous fully-integrated physically-based simulations that have included conceptualization of peatlands is provided in **Table 1**. Use of a simplified representation of peatlands in models is common, even in modeling studies directly focusing on the role of peatlands in local settings (Thompson et al., 2015, 2017), in watershed functioning (Hwang et al., 2018), or as part of a study site landscape (Ala-aho et al., 2015; Smerdon et al., 2007). The effect of simplified treatment of peatland in models is unknown, especially the implications for the magnitude and spatial distribution of fluxes. Therefore, peatland conceptualization should be thoroughly investigated before fully-integrated models are widely used as predictive tools to address the question of how these systems might respond to anthropogenic change. Heterogeneity in the hydraulic properties of peat is difficult to quantify at high spatial resolution (Hare et al., 2017; Holden & Burt, 2002; Koch et al., 2017; Quillet et al., 2017; Rossi et al., 2012). However, techniques for determining the geometry and bulk hydraulic properties of peat layers using soil cores, in situ hydraulic measurements, or non-invasive geophysical techniques are more readily available, and could be better conceptualized into numerical models.

The aim of the present study was to determine the importance of features of the aquifer-mire system, such as soil layer geometry and peat soil properties, when simulating GW-SW exchanges. Particular attention was paid to the implications of using the models as predictive tools for assessment of human impacts on groundwater-dependent peatlands. Steady-state conceptual model (CM) simulations of an idealized hypothetical hillslope representing a typical boreal aquifer-mire transect were conducted using the fully-integrated physically-based code HydroGeoSphere. Use of a hypothetical hillslope steady-state model provides several advantages over models of actual field sites. Numerical experiments allow the importance of target factors to be assessed in a transparent manner under a variety of topographical and hydrogeological settings, while a generic simulation set-up and use of dimensionless parameters allow transferability of concepts and results. Specific objectives of this study were to:

- Quantify the effect of peat soil geometry representation in a fully-integrated GW-SW model on the magnitude and spatial distribution of GW-SW exchange fluxes in a hypothetical hillslope transferable to different environments

- Employ different simulation scenarios and dimensionless variables to study other potential factors controlling the location and magnitude of groundwater discharge, in addition to peat soil geometry

- Apply the generic simulations to examine the vulnerability of the peat-hillslope system to long-term land use influences such as climate change and groundwater level decline due to abstraction.

2 Methods

2.1 Conceptual model for the simulated hillslope

In our conceptual model, the interface between a typical boreal groundwater-dependent peatland and mineral deposits is represented by a 1000 m long two-dimensional (2D) hillslope profile (**Fig. 1a**). Starting at the maximum topographical height (left boundary of the model), the land elevation decreases linearly towards the peatland area, representing an aquifer. At the peatland, the slope declines to represent the typical peatland flat topography. Consequently, the lowest point is at the right boundary of the model domain (**Fig. 1a**). The slope varies with the conceptual model type studied (see subsection 2.4). Model parameters need to be defined separately for the subsurface flow domain and overland flow domain for the numerical model application (see subsection 2.2.1). The mineral soil of the subsurface layer, referred to hereafter as the 'mineral soil zone', includes the saturated and unsaturated soil layer covered by forest vegetation. The overland flow domain on the mineral soil is referred to hereafter as 'overland mineral. The overland and subsurface flow domains in the peat are referred to individually as 'overland peat' and 'subsurface peat', and collectively as the 'peat zone'. In the present study, microtopography was represented by overland domain properties, and rill and obstruction storage parameters, with distinct values for each zone (Frei & Fleckenstein, 2014).

Groundwater-dependent peatlands act as transition zones between groundwater systems and surface water environments. The exact GW-SW interface, i.e., the subsurface region proximal to surface water bodies (McLachlan et al., 2017), can be difficult to define for peatland environments. For this reason, in the present study the GW-SW interface was conceptualized in two different ways. The first conceptualization was the interface between mineral soil and peat soil in the subsurface domain (GW-peat interface; **Fig. 1a**). The groundwater flux through this interface, i.e., the total amount of groundwater discharging to the peatland (hereafter referred as 'the flux through the bottom of the peat') affects the microbiological activity (Lin et al., 2012; Mitchell & Branfireun, 2005). However, this flux does not necessarily reach the peat surface and may not be available for peat vegetation. Thus, the boundary between the overland and subsurface domains of the numerical model was considered as another interface (peat-SW interface; **Fig.1a**).

2.2 Numerical model implementation

2.2.1 HydroGeoSphere

Numerical modeling was conducted using the fully-integrated physically-based code HydroGeoSphere (Aquanty, 2015). HydroGeoSphere is a control-volume finite-element modeling software that simultaneously solves the Richards equation (Richards, 1931) and 2D diffusion-wave Saint-Venant approximation to represent flow processes in subsurface and overland flow domains, respectively. The implicit simultaneous solution of the governing equations provides a direct representation of feedbacks between the porous domain and surface

domain, which enables autogenesis of surface water body features; i.e., rivers and lakes are formed in topographical depressions in a physically-based way (Brunner & Simmons, 2012). These features make the HydroGeoSphere code suitable for modeling GW-SW exchange fluxes. HydroGeoSphere has been successfully applied in studying GW-SW interactions in peat-dominated environments at various scales (e.g., Frei & Fleckenstein, 2014; Hwang et al., 2018; Liu et al., 2016; Smerdon et al., 2007; C. Thompson et al., 2015). Recent studies by Ala-aho et al. (2015, 2017) and Glaser et al. (2016) show that, if properly calibrated, the HydroGeoSphere model is also able to reproduce GW-SW exchange patterns in riparian headwaters and lakes. For a detailed description of HydroGeoSphere capabilities, theory, and numerical implementation, see the software manual (Aquanty, 2015).

2.2.2 Model mesh

The subsurface model domain was discretized using 1 m square elements in the horizontal direction and 0.1 m elements in the vertical direction for the top domain down to 4 m depth. Elements below 4 m depth in the model domain varied in vertical thickness, with thickness increasing towards the bottom. In total, the subsurface part of the model comprised 72 vertical layers, 146,146 nodes, and 72,000 elements. For the numerical model solution, the mesh was extended to a third dimension with a unit width of 1 m. During model solution, the blocks were further subdivided into tetrahedral elements, in order to decrease the numerical error related to negative transmissivities (Letniowski & Forsyth, 1991).

2.2.3 Boundary conditions and running settings

Boundary conditions applied to the subsurface model domain consisted of no-flow at the bottom of the model domain and constant head boundary conditions at the right and left edges (**Fig. 1a**). The no-flow boundary at the bottom portrays relatively impermeable and hydrologically inactive bedrock. The constant head boundary conditions were selected to mimic a peatland-mineral deposit interface cross-section. The constant head boundary condition on the left was equivalent to a depth to groundwater of 10 m. This is within the range typical for boreal shallow groundwater systems (e.g., Okkonen & Kløve, 2011; Quillet et al., 2017; Rossi et al., 2012). At the right edge of the domain, the constant head was set to equal the land elevation. This boundary condition represents a regional surface water feature such as a river or lake.

Surface water was allowed to freely exit the model by assigning a critical depth boundary condition to the top nodes at the right edge of the model domain. For simplicity, no rainfall (zero flux) boundary conditions were applied to the top of the model. The boundary conditions applied enabled us to study the effects of peat layer geometry and of other system features on GW-SW exchange fluxes without introducing unnecessary complexity. A dual node approach was used for coupling surface and subsurface flow. This method uses first-order leakage relation similar to Darcy flux to describe the exchange flux between domains separated by a thin 'imaginary' layer interface defined by a coupling length l_{exch}, a non-physical parameter estimated to preserve- near-continuity of pressure between the overland and subsurface flow domains (Ebel et al., 2009; Liggett et al., 2012). Coupling length $l_{exch} = 0.001$ m was chosen according to recommendations by Liggett et al. (2012). The parameter value was assessed by conducting sensitivity analysis using values $l_{exch} = 0.01$ m and $l_{exch} = 0.0001$ m. In most of the model set-ups tested, model outputs were insensitive to coupling length. The quasi-steady-state solution was accomplished by executing a transient state model and allowing the model to drain over the arbitrary 1000-year period with a variable time step. The steady-state solution was verified by checking rate of change of storage for the entire model domain, which should be approximately 0.

2.3. Conceptual models to study features influencing GW-SW water exchange

The effects of peat layer geometry and of other system features on GW-SW interactions were evaluated using conceptual model simulations by sequentially changing various model characteristics (**Table 2**). This included comparing the outputs of models with varying peat soil layer geometries (including a case without a peat layer), soil hydraulic conductivities (peat and mineral soil zones), domain slope, vertical discretization, and boundary conditions. The whole subsurface domain of the reference model consisted of sand soil, but different overland flow properties were assigned to the peat and mineral soil zones (Table 2). The surface properties were the same in all CMs studied.

The effect of peat depth representation was studied by considering three conceptual geometries (CM 1b-d in **Table 2**). These were: uniform, depth increasing logarithmically, and a realistic geometry soil layer representation based on actual data (hereafter referred to as 'the case study CM') (**Fig. 1b**). Simulations with peat data from a case study allowed us to compare the influence of increasingly complex peat layer geometries in our hypothetical hillslope. In the case study CM, peat depth distribution was derived from peat thickness data on the Mesisuo-Sarvisuo bog-fen complex in Finland, by extracting peat depth cross-section in the middle part of the peatland from data produced by ground-penetrating radar surveys (Isokangas et al., 2017). The average peat depth of this transect totaled 2.41 m, and peat geometry CMs 1b and 1c were built in such a way that their average peat depth was also 2.41 m. The logarithmically increasing peat depth d varied according to the function:

$$d(x) = p \cdot \log_{10} x \qquad\qquad (1)$$

where p is a scaling constant introduced to create a peat depth distribution that results in 2.41 m average depth of the peat layer (here $p = 1.0606$) and x represents the distance from the peatland origin.

The effect of the surrounding soil hydraulic properties was tested by simulating all four geometry CMs for sandy soil (CMs 1a-d) and glacial till soil (CMs 2a-d). The subsurface and overland flow domain parameters were defined using literature values and selected to reflect the commonly observed distinctive difference between hillslope and peatland landscape units (**Table S1** in Supporting Information). The overland flow domain included 'overland peat' for the 500-1000 m zone and 'overland mineral' for the 0-500 m zone for all peat geometry CMs tested, including the 'no peat' case, in order to exclude the effect of overland properties on flow configuration. For simplification purposes, each soil type was assumed to be isotropic and homogenous. The soil water retention characteristics applied are presented in **Fig. S1** in the Supporting Information.

The effect of peat hydraulic conductivity (K_{peat}) on GW-SW exchange flux patterns was investigated in CMs 3a-3d by changing the hydraulic conductivity for the uniform and case study peat soil layer representations by two orders of magnitude. To make the analysis more general and transferable to other landscapes and geologies, a dimensionless parameter ratio of hydraulic conductivity in peat and sand (K_{peat}/K_{sand}) was used to study how this ratio controlled the effective exchange fluxes in different peat soil layer geometry CMs. Peat hydraulic conductivity was varied from 1.0E-9 to 1.0E-5 m/s, while sand hydraulic properties were kept constant.

For transferability of the findings to other aquifer-peatland systems, the slopes in the conceptual model simulations were defined to represent typical relief of the boreal landscape. The slopes were determined for esker areas previously studied by Isokangas et al. (2017) and Eskelinen et al. (2015) to represent esker site characteristics, and peatlands in the Pallas area of northern Finland investigated using topographical maps (National Land Survey of Finland,

2014), to represent fell site characteristics. The sites were chosen to represent contrasting landscape types, i.e., mild relief eskers and steep fell regions present in boreal peatland zones. Slope steepness is a specific hillslope characteristic that usually depends on the distance over which it is evaluated. The calculated slope of esker relief varies between 0 and 3% for the Rokua esker (Eskelinen et al., 2015), and between 2.5% and 3.5% for the Viinivaara aquifer, while peatlands have been found to have slopes of around 0.5% over the whole length of the peatland . Based on these ranges, it was decided to use a slope of 3% for the esker area and 0.5% for the adjacent peat zone. The peatlands in the Pallas area are surrounded by mineral deposits with slope varying between 5% and 26%, while the slope of the peatlands ranges between 0.2% and 8% (National Land Survey of Finland, 2014). Accordingly, it was decided to use a site slope of 10%, as done in a previous study to describe sites of moderate slope (Gleeson & Manning, 2008), and a slope of 4% for the peatland zone (CMs 4a-4d). The total thickness of soil deposits was set to be the same as in the mild slope models (CMs 1a-1d).

The general influence of slope steepness on normalized effective exchange fluxes was studied by varying the slope of the mineral soil zone and peat zone. This was done for two peat soil layer geometries in the mild slope set-up. First, the slope of the mineral soil zone was altered from 1% to 5% while keeping the peat zone slope constant at 0.5%. Then, the slope of the peat zone was altered from 0.3% to 1.5% while the slope of the mineral soil zone was kept constant at 3%. The changes in normalized effective exchange fluxes are reported with dimensionless ratios between the slopes in the two scenarios.

Vertical and horizontal discretization of the model mesh was expected to have an effect on peat geometry implementation in the model, due to the way in which the mesh was built, and thus to affect the model outputs. The effect of horizontal discretization on model accuracy is a well-recognized issue. Previous studies have shown that horizontal discretization has a larger impact on model results than aggregation of soil hydraulic properties (Sciuto & Diekkrüger, 2010), due to poor representation of the surface water network in coarser meshes and smoothing of surface slopes (Sciuto & Diekkrüger, 2010; Wildemeersch et al., 2014). Recalibration of the model may partly compensate for errors related to grid coarsening (Refsgaard, 1997; Wildemeersch et al., 2014). The effect of model vertical discretization has been given little consideration, and then mainly in respect of numerical challenges in accurate solution of the Richards equation (Downer & Ogden, 2004; Vogel & Ippisch, 2008). It has also been recognized that vertical discretization of the model affects the magnitude of vertical fluxes in the unsaturated zone (Blessent et al., 2017; Carrera-Hernández et al., 2012). Tetrahedral elements tend to create a 'stair-like' boundary between peat and mineral soil for irregular peat geometries. For this reason, sensitivity of the model to discretization was investigated (CMs 5a-e) for the no peat and case study peat soil layer representations by evaluating two cases: i) vertical discretization of 5 cm (half that in CMs 1a and 1d, and CMs 5a and 5c, for the no peat and case study peat soil representation, respectively); and ii) vertical discretization of 20 cm (twice that in CMs 1a and 1d, and CMs 5b and 5d, for the no peat and case study peat soil representation, respectively). In addition, the actual peat depths for the case study peat soil geometry representation were investigated by applying proportional layering within the peat layer, which produced layers with variable thickness that exactly matched the geometry of the interpolated ground-penetrating radar data (CM 5e).

Changes in groundwater levels, mimicking climate variability or groundwater abstraction, were investigated for the uniform (CMs 6a-f) and case study peat soil layer representation (CMs 7a-f) by adjusting boundary conditions at the left edge of the model domain. Profile models are not appropriate to simulate three-dimensional (3D) effects such as radial flow to a pumping well (Anderson et al., 2015), but the long-term effects can be investigated by changing the groundwater level configuration of the modeled system. Wet

conditions were obtained by raising the specified head boundary condition of 0.5 m, while the effect of groundwater pumping was studied by decreasing the specified head by 0.5 m and 1 m until no GW-SW exchange flux in the peatlands was observed. This was equivalent to a specified head of 13.5 m.

3 Results

3.1 Effect of peat geometry on groundwater levels and GW-SW interactions

The peat soil layer geometry representations (CMs 1a-d) had only a slight effect on groundwater levels in the mineral soil zone and no impact on those in the peat zone (**Fig. 2a**). The groundwater level intersected with the land surface in the mineral soil zone near the peatland edge (494-499 m from the left model boundary). The groundwater elevations were overall similar for different peat soil layer geometries, with a maximum difference in elevation of 0.09 m close to the point of groundwater intersection with the land surface. The uniform peat CM (1b) showed the highest groundwater levels. The logarithmically changing and case study peat soil layer geometries (CMs 1c and 1 d) resulted in lower, but very similar, groundwater levels, whereas the model with no peat (CMs 1a) generated the lowest groundwater elevations.

Presence of a peat layer and its geometry affected groundwater flow paths (**Fig. 3**). In all peat geometry cases (CMs 1a-1d), shallower groundwater discharged at the break in slope, visible as converging streamlines. In contrast, flux through the bottom of the peat was fed by deeper groundwater and the flow paths were controlled by peat geometry. The deepest groundwater passed under the overlying peatland and was removed from the model by the right-hand side boundary condition, without contact with the peat layer.

The peat soil layer geometry CMs (1a-d) produced distinctly different GW-SW exchange flux patterns (**Fig. 2b**). In the no peat CM (1a), the exfiltration rate decreased faster with increasing distance from the beginning of the peat zone than for the CMs including peat (1b-d), and remained constant but small in magnitude over a large part of the peat zone (~470 m). The change into the infiltration zone occurred abruptly and infiltration rate reached the highest values at the end of the peatland. In all CMs including peat (CMs 1b-d), groundwater started to discharge with low flow rates at 3-6 m before the peat-mineral soil interface in mineral soil, followed by the highest exfiltration rates at the interface, which is coincident with the break in slope. The exfiltration in the peat zone was slower than in the mineral soil zone before the break of slope, and gradually decreased along the slope. However, it was larger than for the no peat model (CM 1 a) and, importantly, occurred over a long distance (305-457 m). At a certain point in the peatland, exchange dynamics changed from exfiltrating to infiltrating. The location of this point differed between the various peat soil layer geometries. The difference was especially apparent for the case study peat soil layer geometry (CM 1d), while uniform peat (CM 1b) and logarithmically changing peat soil layer (CM 1c) geometries resulted in similar GW-SW exchange flux patterns. In the uniform peat and logarithmically changing peat soil layer geometries, GW-SW exchange flux transition from positive to negative values occurred at similar locations from the beginning of the peat zone, at ~450 m for the uniform (CM 1b) and ~457 m for the logarithmically changing (CM 1c) soil layer representations. For the case study CM (1c), exchange flux occurred closest to the beginning of the peatland zone (~305 m from the start of the peatland).

For the geometries tested (CMs 1a-d), total groundwater flux through the bottom of the peat and the exfiltration component of GW-SW exchange flux in the whole domain were similar overall in all CMs, ranging from 1.05E-06 to 1.16E-06 m^3/s and from 1.13E-06 to 1.16E-06 m^3/s, respectively. Numerical results of different CMs are summarized in **Table S2**

and presented graphically in **Fig. S2** in Supporting Information. The water balance components for various CMs differed in respect of the amount inflowing and outflowing through the boundary conditions (**Fig. S2** in Supporting Information). For comparison purposes, the effective exchange fluxes to the overland domain (spatially integrated GW-SW exchange flux over the mineral soil zone and peatland zone) and flux through the bottom of the peat were normalized by dividing these variables by the total influx through the left-hand side boundary condition. The normalized effective exchange flux to the mineral soil and peatland zones varied for each peat layer geometry representation (**Fig. 4a, Table S2**). The proportion of water discharging through the peat was highest in the logarithmic peat soil layer representation (CM 1c, 74.0%), followed by the uniform peat soil geometry (CM 1b, 72.4%), while it was lowest in the case study peat representation (CM 1d, 71.2 %). In the no peat case (CM 1a), the groundwater inflow to the surface was significantly less (47.3 %) than in the models with a peat layer in both mineral soil and peat zone.

3.2 Effect of soil type (glacial till vs sand, slope, peat hydraulic conductivity)

The infiltration/exfiltration behavior in glacial till soil (CMs 2a-d) and sandy esker soil (CMs 1a-d) in mild slope models was similar in terms of normalized effective exchange flux (**Fig. 4a, 4b**). The normalized effective exchange flux was on average 3.7% higher for the peat zone and 2.6% lower for the mineral soil zone in the glacial till models (CMs 2a-d) than the sand soil models (CMs 1a-d). In terms of absolute values, the effective exchange flux in glacial till soils was 56% and 65% lower in the peat and mineral soil zones, respectively (**Fig. S2** in Supporting Information).

The change in peat hydraulic conductivity moderately affected the amount of water flowing through the boundary conditions, groundwater elevation (mean change in the mineral soil zone was 1-2 cm), and the amount of flux through the bottom of the peat (absolute maximum change was 4.4%). For more details, see **Table S2 and Figure S2** in the Supporting Information. However, the alternating peat hydraulic conductivity produced different exchange flux patterns for the two geometries investigated, i.e., the uniform peat and case study peat layer geometry representations (**Fig. 5**). In the lower hydraulic conductivity cases (CM 3a and 3c; **Fig. 4d**), the normalized effective exchange flux was higher in the mineral soil zone than in the initial models (CMs 1b and 1d), whereas the reverse was true for the higher hydraulic conductivity CMs (3b and 3d). A 10-fold decrease in peat hydraulic conductivity led to a decrease in the normalized effective exchange flux of 15% and 18% in the peat zone of the uniform and case study peat soil geometry representations, respectively. A 10-fold increase in conductivity produced 10% and 5% higher effective exchange flux in the peat zone of the uniform and case study peat soil layer geometries, respectively.

A plot of soil hydraulic conductivity ratios versus effective exchange flux (**Fig. 6a**) showed that the total normalized effective exchange flux was approximately constant for K_{peat}/K_{sand} ratios smaller than 0.01 (i.e., when the hydraulic conductivity of peat was two orders of magnitude smaller than the hydraulic conductivity of sand), and decreased for higher K_{peat}/K_{sand} ratios. In the mineral soil zone, the normalized effective exchange flux was highest for the case with the lowest peat hydraulic conductivity (i.e., the lowest K_{peat}/K_{sand} ratio), and decreased with increasing K_{peat}/K_{sand} ratio. The normalized effective exchange flux to the peat zone reaches its highest value when the K_{peat}/K_{sand} ratio was 0.1, and decreased with lower and higher ratios.

In the moderate relief models (CMs 4a-d, **Fig. 4c**), the fluxes through all defined boundary conditions (constant head on the left and right edge of the model domain, critical depth on the right edge) and through the peat-mineral soil interface were approximately one to

two orders of magnitude higher than the corresponding fluxes in the mild slope models (CMs 1a-d). The effective exchange flux was on average 625% higher for the peat zone and 1508% for the mineral soil zone (see **Fig. S2** in Supporting Information). Thus, for all peat geometries, a larger proportion of effective exchange flux occurred already in the mineral soil zone. This large difference in effective exchange fluxes was because the steeper slope models were associated with higher hydraulic gradients. Consequently, more water was transmitted through the model domain (on average 827% more) and discharged to the surface domain. The proportion of effective exchange flux in the peat zone to effective exchange flux in the whole model was lower in the moderate slope models than in the mild slope models (CMs 1b-d), but followed the same dynamics as in the mild slope models. The proportion of water discharging through peat was highest in the case study peat soil layer geometry representation (54% of total normalized effective exchange flux), and lowest in the uniform peat representation (31% of total normalized effective exchange flux).

A general analysis to compare different slopes of the mineral soil and peat zones using $Slope_{peat}/Slope_{sand}$ ratios showed that, for most of the ratios tested, the normalized effective exchange fluxes did not change with varying slope of the mineral soil (peat zone slope kept constant at 0.5%) (**Fig 6b**). The only exception was the highest $Slope_{peat}/Slope_{sand}$ ratio (0.5) for the uniform soil layer geometry. This case corresponded to a mild mineral soil zone slope of 1% and resulted in water elevation being equal to the land surface elevation through the whole hillslope. In the uniform peat soil layer geometry case, the peat layer at the edge of the peatland was thicker than in other cases, and forced more groundwater to discharge already in the mineral soil zone, whereas the total normalized effective exchange fluxes remained similar for all varying mineral soil zone slopes. In contrast, the normalized effective exchange fluxes were sensitive to varying peatland slope (mineral zone slope was kept constant at 3%). The highest normalized effective exchange fluxes to both peat and mineral soil zones occurred for the smallest $Slope_{peat}/Slope_{sand}$ ratio (0.1). The normalized effective exchange fluxes for both peat and mineral zones decreased with increasing $Slope_{peat}/Slope_{sand}$ ratio (corresponding to a smaller contrast between peat and mineral soil zone slopes) and approached zero approximately for $Slope_{peat}/Slope_{sand}$ ratio = 0.4.

3.3 Exchange flux sensitivity to vertical discretization

The choice of discretization had no impact on GW-SW exchange flux for the no peat model (CMs 1a, 5a and 5b in **Fig. 7;** CMs visible as one line). In the case study peat soil layer geometry representation (CMs 1d and 5c-e), a more sparsely discretized model produced a 'stepwise' effect on the spatial GW-SW exchange flux (**Fig. 7**) and slightly modified other output variables. For instance, a change in the discretization from 10 cm (CM 1d) to 5 cm (CM 5c) for the case study peat soil layer geometry representation increased the normalized effective flux by 4% in the mineral soil zone and decreased it by 1% in the peat zone, compared with the original model (CM 1d). For case study CMs (5c-e), the magnitude of the normalized flux through the bottom of the peat and groundwater elevation was only slightly affected, e.g., the maximum groundwater elevation difference from the original CMs (1d) was around 0.05 m and the maximum change in the normalized flux through the bottom of the peat was around 0.5% (for more details, see **Table S2**).

3.4 Exchange flux sensitivity to changes in aquifer water level

Long-term groundwater abstraction/wet conditions were represented in the model by changing (decreasing/increasing) steady-head boundary conditions at the left edge of the model to reflect changes in groundwater configuration of the aquifer. A groundwater head increase of 0.5 m at the left boundary condition (CM 6a and 7a) from the reference CMs (1b and 1d) led

to on average a 0.28 m rise in the groundwater level in the mineral soil zone (first 500 m of the model domain) for both the case study and uniform peat soil geometry representations. Lowering the boundary condition of 1 m from the reference CM (1b and 1d) decreased the groundwater level by on average 0.55-0.56 m. In contrast, the groundwater level in the peat zone was little affected by the change in boundary conditions (**Table 3**). Groundwater elevation in the peatland was equal to the land surface until the boundary condition dropped below a certain threshold (in the model 14.5 m, corresponding to drawdown of 3 m). The maximum groundwater level declined in the peatland zone by 0.13 m for the uniform and 0.16 m for the study case peat soil layer representations, at a boundary condition of 13.5 m.

In contrast, the effective exchange flux was very sensitive to changes in boundary conditions (**Table 3**) and a clear transition occurred from high groundwater dependence to a system with no groundwater input (**Table 3**). Exchange flux in different CMs indicated that the lower constant head boundary conditions mainly reduced the magnitude of groundwater exfiltration in the first 150 m of the peat zone (X=500-650 m), which was evident as reduced positive GW-SW exchange flux values at this distance (**Fig. 8**). Below the threshold, the steady head boundary condition was 14.5 m in the uniform and 15.5 m in the case study peat soil layer geometry, corresponding to a groundwater drawdown of 3 m and 2 m, respectively, and the beginning of the exfiltration zone shifted towards the center of the peatland. Below these threshold values, the overall length of the exfiltration zone diminished with decreasing groundwater elevation in the aquifer, whereas the transition into the infiltration zone occurred at approximately the same location. When the groundwater configuration was deep enough (in the model corresponding to a steady head boundary condition of 13.5 m; CMs 6g and 7f), no exchange flux occurred in the whole peatland, seen in **Fig. 8** as horizontal yellow lines over the x-axis. Similarly, decreasing groundwater levels affected the overall amount of flux through the bottom of the peatland (**Table S2** in Supporting Information). A drawdown of 3.5 m at the left boundary led to a 98% and 97% drop in the flux through the bottom of the peat for the uniform (CM 6e) and case study (CM 7e) peat soil layer representations, respectively, in comparison with the reference cases (CMs 1 b and 1d).

4. Discussion

4.1 Importance of peat soil representation for the location of simulated GW-SW interactions

Hypothetical hillslope simulations of an aquifer-peatland system under a variety of settings helped to identify the key factors influencing simulated GW-SW interactions in groundwater-fed boreal peatlands. The chosen approach of using a hypothetical hillslope set-up makes the findings general and the concepts transferable to similar aquifer-peatland systems. The results revealed that the peat soil layer geometry representation (CMs 1b-d) had a minor effect on the total magnitude of the exchange fluxes, but it clearly impacted the spatial variability of GW-SW interactions (**Fig. 2b**). Changes in peat layer geometry affected groundwater flow paths (**Fig. 3**), despite the groundwater elevation being only slightly affected within the mineral soil zone and totally unaffected in the peat zone (**Fig. 2a**). These results indicate that simulated effective exchange fluxes are sensitive to how the peat depth is represented. The spatial distribution of groundwater discharge and recharge, and local GW-SW flux values, will most probably be incorrect or inaccurate for simplified peat layer representations (such as CMs a and b), if the actual peat soil layer depth varies considerably within modeled systems. Inclusion of a peat soil layer is crucial when a peatland-dominated landscape is modeled. Simplified representation of a landscape in large-scale models in which small peatland areas are omitted can lead to incorrect GW-SW exchange patterns and errors in

overall magnitude of effective exchange flux within the studied landscape. This is seen as the clear difference in the simulation results for the model with no peat representation (CM 1a) in comparison with different peat soil geometry representations (CMs 1b-d) in terms of GW-SW distribution and normalized effective exchange flux.

Peat layer geometry will have some effect on the proportion of water discharging to the peat and mineral soil zones, by determining how much of the groundwater will discharge in the mineral soil zone and how much will discharge further downslope in the peat zone. According to our results, thick peat deposits located immediately at the aquifer edge favor higher groundwater discharge to the mineral soil zone. This is consistent with findings by Lowry et al. (2009) that the location of the peat-mineral soil interface controls groundwater flow path in mires and that the occurrence of large springs and ponds is related to the break in slope occurring in the peat soil layer.

The hydraulic conductivity of mineral soil had rather a minor impact on the proportions of exchange fluxes in both the peat and mineral soil zones (**Fig. 4b**), but strongly controlled the magnitude of flux through subsurface boundary conditions and thus significantly affected the overall magnitude of GW-SW interactions **(Fig. S2).** Better conducting mineral soils have the capability to produce higher GW-SW exchange fluxes. In some cases, this may have important implications for modeling GW-SW interactions in peatlands, as reliable measurement of the mineral soil hydraulic conductivity at larger scales is challenging and small-scale features of flow may be misrepresented in the model. In many cases, springs are located in areas that display   differences in hydraulic conductivity (Fetter, 2014).

Peat hydraulic conductivity had a clear effect on the magnitude of GW-SW interactions at the peat surface and their spatial variability **(Fig. 5 and 6a)**, whereas the flux through the bottom of the peat was significantly less affected. Higher peat hydraulic conductivity allowed more water to be conducted near-horizontally within the peat layer. This also allowed for more intense exchange between the subsurface and overland domains. In contrast, lower peat hydraulic conductivity forced a larger proportion of groundwater to discharge already in the mineral soil zone, and decreased GW-SW interaction in the peat zone. Thus, GW-SW dynamics are closely related to the hydraulic properties of peat, as suggested in previous studies (Fraser et al., 2001; Waddington & Roulet, 1997). The impact of a 10-fold decrease in peat hydraulic conductivity on normalized effective exchange flux to the peat and mineral soil zones (CMs 7a and 7d in **Fig. 4d**) was comparable to the difference between the uniform and case study peat soil layer geometry representations (CMs 1a and 1d in **Fig. 4a**).

Analysis of hydraulic conductivities using dimensionless parameter ratios revealed that not only the absolute value, but also the contrast between peat and mineral soils is a key factor in understanding the intensity of GW-SW exchange fluxes. Interestingly, the results showed that the peatland exchange fluxes were highest for a K_{peat}/K_{sand} ratio of around 0.1 (**Fig. 6a**). Relatively high hydraulic conductivity of peat allowed substantial flows from hillslope to peatland, whereas a sufficient difference in hydraulic conductivity promoted discharge to the mineral soil zone too. Hydraulic conductivities of peat lower than the 0.1 ratio inhibited exchange between surface and subsurface, whereas higher values promoted flow within the peat matrix parallel to the land surface and resulted in lower GW-SW interactions. In the mineral soil zone, low ratios (low peat hydraulic conductivities) correlated with higher groundwater discharge into the mineral soil part of the slope, as lower peat hydraulic conductivity forced a greater proportion of water to be discharged to the mineral soil zone. These findings emphasize that accurate estimates of the hydraulic conductivities of peat and mineral soil and of peat geometry are essential in correctly representing GW-SW exchange fluxes. Using dimensionless ratios instead of absolute values allows transferability to other

systems and facilitates quantitative site comparison. For K_{peat}/K_{sand} ratios ≤0.1, low GW-SW exchange is more likely to be limited by low peat permeability, whereas above this ratio the groundwater exfiltration flux to the surface becomes more unlikely due to lateral flow in the peat.

Our results show that the effect of peat soil layer geometry on the proportions of water discharging to the peat and mineral soil zones may be stronger in systems with steep slopes. Land slope also controls the overall magnitude of effective exchange flux, as overall higher hydraulic gradients have the potential to allow more water to be transmitted through the model domain. In addition to slope, water flowing through any natural system would also be constrained by the amount of groundwater recharge, which was not a limiting factor in our simulation setup due to constant head boundary. It has been reported previously that steeper land slope is associated with intensification of local flows (Gleeson & Manning, 2008; Tóth, 1963). To generalize our simulations to other settings, we analyzed slope ratios of the peat and mineral soil zones. The results suggest that peatlands with relatively flat slope can be expected to have high GW-SW interactions, whereas peatlands located within hillslopes with low contrast between slopes can be expected to have lower GW-SW interactions.

According to our analysis, slope of the mineral soil has a minor influence on effective GW-SW exchange flux. Different representation of peat thickness in the model (uniform vs case study scenarios) was important only with the steepest mineral soil zone slopes tested, if the groundwater level followed mineral soil zone slope (**Fig. 6b**). In contrast, peat zone slope strongly influenced the amount of groundwater discharging to the mineral and peat zones. A high contrast between the slopes (strong break in slope, low $Slope_{peat}$ / $Slope_{sand}$ ratio) favored groundwater discharge in both peat and mineral soil zones, whereas no or small contrast (weak break in slope) promoted subsurface flow and little interaction between the subsurface and surface domains. To transfer the results to other sites, the analysis suggests pronounced GW-SW interactions primarily in peatlands where the peatland slope is flat in comparison with adjacent hillslopes. Eskelinen et al. (2015) used mineral soil slopes using GIS analysis to identify GW-SW interaction hotspots in peatlands, but our results suggest that the analysis could be more informative if extended to account also for peatland slopes.

In comparison with the effect of other variables, model vertical discretization had only weak effects on simulated normalized effective exchange fluxes. This indicates that the model is not very sensitive to vertical resolution when the model domain is sufficiently discretized and does not create large errors in the model water balance. Model discretization may still lead to variations in the fluxes obtained, especially when it affects the hydraulic properties assigned to given elements. For instance, the no peat CMs produced similar exchange flux patterns for the discretization tested, whereas the proportional layering of the case study soil geometry produced 13% higher and 5% lower normalized exchange fluxes in the mineral soil and peatland zones, respectively, than in 10-cm layering. The models with coarser discretization tended to produce shallower groundwater levels (**Fig. S3** in Supporting Information). Previous studies have shown that the sensitivity of models based on the Richards' equation to vertical discretization is mainly attributable to numerical stability issues (see e.g., review by Farthing & Ogden, 2017). Higher resolution results in better solution accuracy, but is also associated with longer computing times. This means that the resolution of vertical discretization should be balanced between simulation accuracy and running times (Carrera-Hernández et al., 2012; Downer & Ogden, 2004). The coarse representation of hydraulic properties provided by a sparser grid may play a more important role for model flux outputs than numerical inaccuracies when the mesh resolution is already high enough and does not result in high water balance errors.

Another issue is that non-continuous increment at the peat-mineral interface soil created a 'stepwise' effect on the GW-SW exchange fluxes (**Fig. 7**), which was especially pronounced in the coarser grids. This seemed to be due to the manner in which the mesh was built and the hydraulic properties assigned to peat (only elements with the centroid above the assigned peat depth were chosen to represent peat soil). Thus, the coarser the mesh, the steeper the stepwise changes in hydraulic properties and in the GW-SW exchange fluxes produced. To date, 'stepwise' implementation of peat depth has only been applied when attempting to include changes in peat thickness in simulations (Ala-aho et al., 2017; Hwang et al., 2018). However, our results suggest that vertical discretization producing possibly a smooth peat representation should be implemented for accurate simulation of shallow groundwater processes in peatland-dominated landscapes.

4.2 Peatland vulnerability to long-term influences (groundwater abstraction, climate change)

Groundwater level configuration (enforced here by specifying a boundary condition) was found to have a profound effect on the magnitude and spatial extent of GW-SW exchange (**Fig. 8**). This finding has immediate management implications, suggesting that fully-integrated GW-SW modeling can be used to estimate changes in the amount of water discharging to peatlands and the resulting alterations in spatial GW-SW exchange patterns.

After a certain level of drawdown, 3.5 m in our simulations, the exfiltration zone was greatly reduced and a decrease in peatland groundwater levels was observed. This was linked to significantly decreased fluxes through the bottom of the peat and effective exchange fluxes at the peat-SW interface. Although water level changes remained relatively small in the peat zone, the stress imposed on peat vegetation may be severe, as mire flora typically tolerate only relatively small changes in water level (Aldous & Bach, 2014; Menberu et al., 2016; Tahvanainen, 2011). Over long periods, persistent groundwater level drawdown in peatland could lead to a transition from unique fen mire groundwater-dependent ecosystems to bog-type peatland where groundwater connection is diminished and the ecosystem is dependent on rain. It is important to note that groundwater level is typically the only parameter monitored in field studies, but does not seem to be a sensitive indicator of changes in GW-SW exchange flux.

4.3 Limitations of our analysis

Our hypothetical steady-state hillslope simulations provided a simple framework to investigate factors influencing the magnitude and spatial distribution of GW-SW interactions in a transparent manner over a range of hydrological and geological settings. However, the model configuration applied has limitations, especially due to the simple model geometry and the strong steady-head boundary conditions, which significantly influence the hydrological behavior of the system. Constant head boundary condition at the top of the hillslope profile allows limitless supply of water though the boundary, whereas in reality the water supply would be limited by available groundwater recharge. In order to extend our analysis from changes in water abstraction to changes in water availability, specified flux boundary condition would be more suitable to simulate variability in groundwater recharge. In our conceptual model, the overland mineral and peat zones were devoid of specific microtopographic profiles. Small-scale peatland microtopography is known to influence peatland runoff generation (Frei et al., 2010, 2012; Frei & Fleckenstein, 2014), and consequently GW-SW interactions at the peat surface. However, the influence is on local and small scale flow paths (peatland hummock-hollow scale, cm to meter), whereas we studied GW-SW interaction at hillslope scale.

Another limitation of this study is that effects of other important peat soil properties, such as heterogeneous structure of peat, vertical layering of peat soil with lower hydraulic

conductivity peat at the bottom and higher in top layers (acrotelm/catotelm model), anisotropy, and dual porosity of peat matrix were not investigated. Previous studies have shown that these properties affect the connection between peatlands and aquifers (Hare et al., 2017; Holden & Burt, 2002; Koch et al., 2017; Quillet et al., 2017; Rossi et al., 2012). As living peat is highly complex and as data representing all peat soil properties are unavailable, the effect of these properties should be thoroughly investigated in future studies to evaluate the impacts of other simplifications.

Finally, data availability continues to be a challenge in modeling GW-SW interaction in aquifer-peatland systems. The overall low sensitivity of groundwater levels in peat soils to the variables investigated here indicates that the current practice of monitoring groundwater levels may not be a sufficient proxy for modeling GW-SW exchange fluxes in peatlands. Highly spatially variable peat properties, small measurement errors in hydraulic head (Post & von Asmuth, 2013; Rau et al., 2019), and inaccurate numerical solutions add to parameter non-uniqueness and may further complicate distinguishing between probable and impossible simulated flow regimes. In previous studies, the information content of classical observations such as hydraulic head and streamflow discharge has been demonstrated to be insufficient for calibration of complex hydrological models (reviewed by Schilling et al., 2019). It has been proposed that formulation of calibration problems could be improved, and the uncertainty of predictions reduced, by using non-conventional observations such as temperature, exchange fluxes, tracer concentrations, and residence times. However, implementation of such is challenging, as it often requires additional integration processes in flow models (Schilling et al., 2019).

There is also still a lack of reliable, direct, non-invasive methods for measuring spatial GW-SW exchange flux patterns in peatlands, to obtain data for calibration and validation of fully-integrated models. Non-direct measurement techniques for quantifying GW-SW exchange fluxes within peatlands could be used to define informative spatial groundwater discharge patterns for the calibration process. For instance, thermal infrared imagery (Briggs et al., 2016; Hare et al., 2015, 2017; Isokangas et al., 2017), geophysical techniques (McLachlana et al., 2017) and stable water isotopes (Isokangas et al., 2017; Levy et al., 2014, 2016) can be valuable methods for distinguishing between groundwater-dependent and rainfall-fed areas within peatlands in studies seeking qualitative information on GW-SW exchange fluxes. Geophysical techniques in particular can provide valuable information on the variability of hydrogeological properties, e.g., hydraulic conductivity, that play important roles in shaping GW-SW interactions. Further integration of water quality, temperature, geophysical, and remote sensing data will hopefully help resolve parameter identifiability issues.

5 Conclusions

Based on numerical simulations in a transferrable hypothetical hillslope, the following conclusions on GW-SW interactions in peatlands can be drawn:

- It is important to consider peat soil geometry when modeling spatial GW-SW exchange patterns and groundwater flow paths in peatlands. When studying the extent of groundwater-dependent mire areas, total groundwater influx to a peatland, or chemical composition of the water, peat hydraulic conductivity should also be considered, as it affects spatial GW-SW exchange patterns and groundwater flow paths.

- Peat geometry is less important when the total flux out of the system is of interest, e.g., the total amount of water discharging to a river or lake instead of the peatland. Groundwater exfiltration to peatlands is most pronounced: (1) when peat hydraulic

conductivity is one order of magnitude lower than that of mineral soil, and (2) when peatland has low slope and the break in slope between hillslope and peatland is pronounced.

- Model vertical discretization has little impact on model outputs when the mesh resolution is sufficiently high, but should be carefully chosen as coarser meshes, combined with discrete peat thickness representation, tend to misrepresent layers of variable thickness and could affect the magnitude of effective exchange flux.

- Long-term groundwater drawdown in proximity of peatlands may not be clearly reflected in groundwater-fed peatland water levels, even if it significantly modifies the magnitude and spatial distribution of GW-SW interaction flux and, overall, the whole water balance of the peatland area. From a management viewpoint, this indicates that monitoring groundwater level alone is insufficient to verify the long-term influence of water abstraction on GW-SW interaction fluxes.

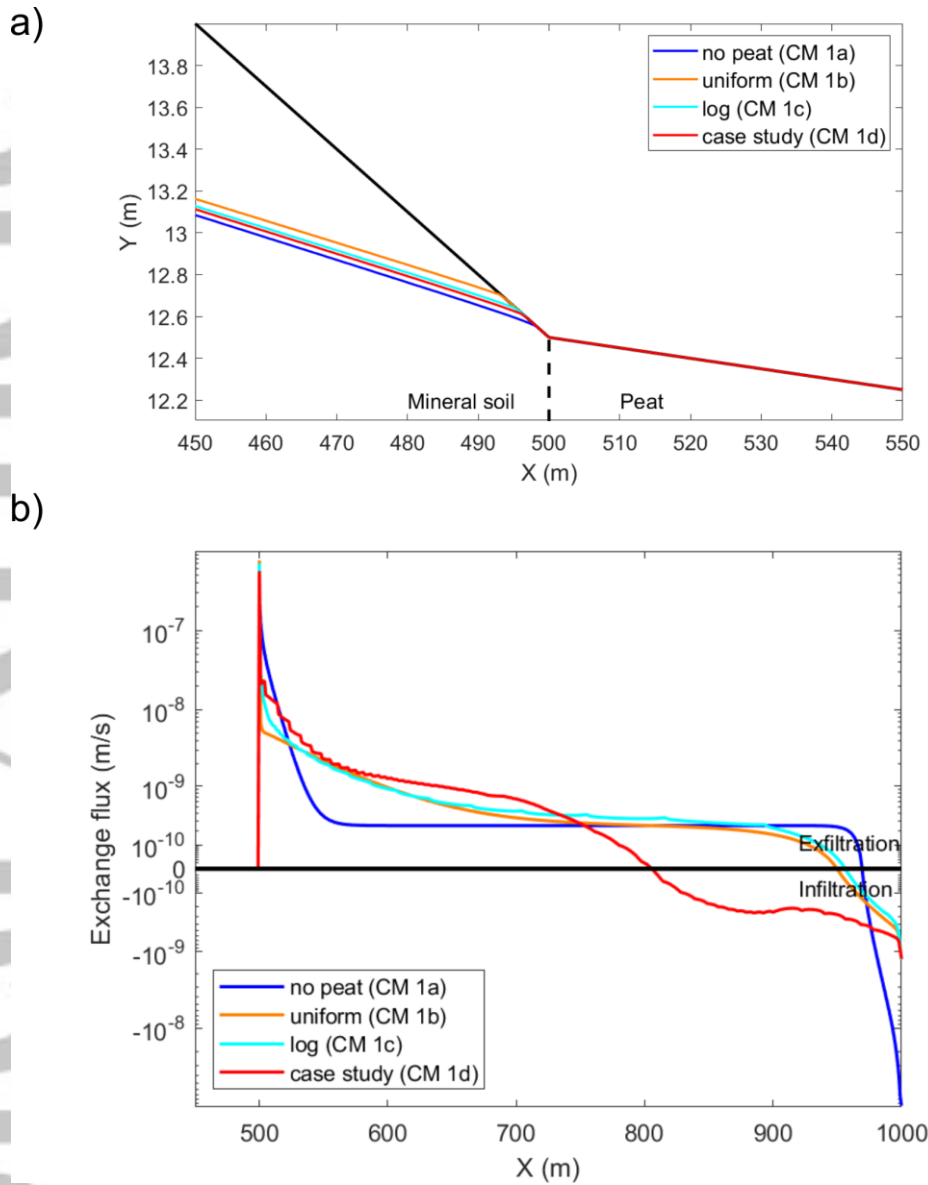

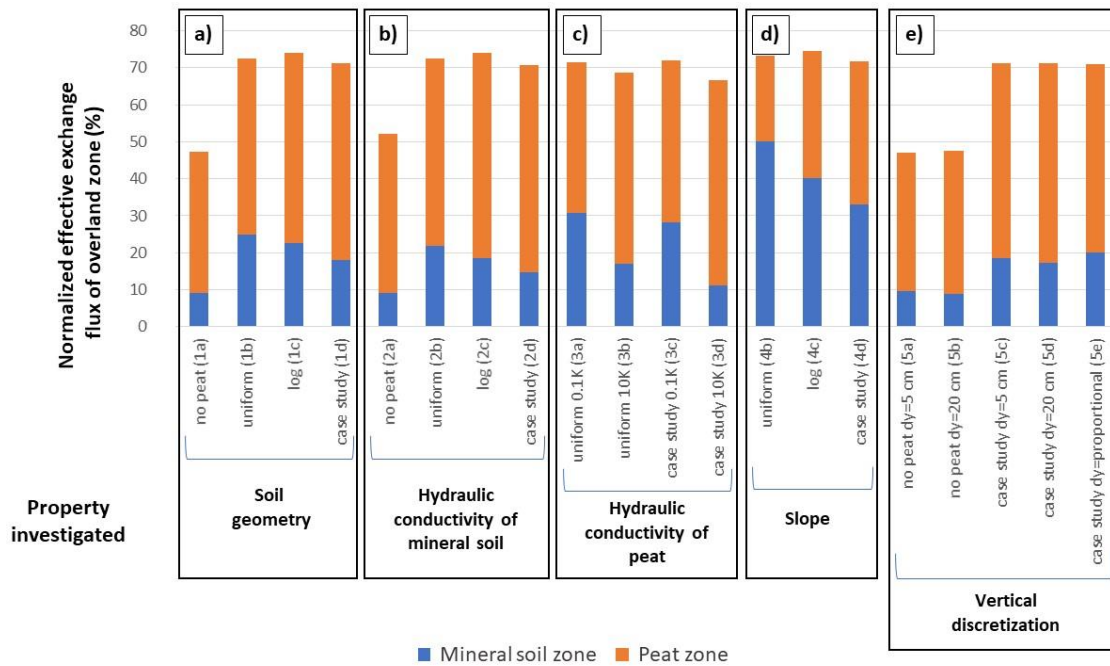

Figure 1. (a) Two-dimensional model domain and conceptualization of GW-SW interfaces in peatlands. 'Overland mineral' and 'overland peat' indicate surface flow zones for forest and peat, respectively. (b) Peat geometry in three types of conceptual models considered in this study.

a)

b)

Figure 2. (a) Detailed diagram of groundwater elevation at the interface of mineral soil and peatland in different peat soil geometry conceptual models (CM). (b) Exchange flux for peat soil layer geometry conceptual models (CMs 1a-d). Positive groundwater-surface water (GW-SW) exchange flux values indicate locations of groundwater discharge to overland zone, negative values indicate areas where water infiltrates to the subsurface. The diagram shows averaged nodal exchange fluxes (total nodal fluxes divided by an influence area of the node), plotted for visualization purposes as a continuous dataset.

Figure 3. Stream traces in the peat soil geometry conceptual models (CM) for (a) no peat (CM 1a), (b) uniform peat (CM 1b), (c) logarithmically changing peat (CM 1c), and (d) case study (CM 1d). Stream traces were generated using Tecplot 360 EX 2015 Release 2.
Figure 4. Normalized effective exchange flux of overland zone in (a-e) different conceptual models (CMs 1-5). Flux is represented as a percentage of the total groundwater inflow through the steady head boundary condition at the left edge of the system. The amount of water flowing through the left boundary condition differed for differing mineral soil hydraulic conductivity and slope cases.

Figure 5. Exchange fluxes for conceptual models (CMs) 4a-d varying the K_{peat}/K_{sand} ratio by differing peat hydraulic conductivity. Plotted with reference to the uniform peat (CM 1b) and case study peat soil layer (CM 1d) geometry representations. Positive groundwater-surface water (GW-SW) exchange flux values indicate locations of groundwater discharge to overland zone, negative values indicate areas where water infiltrates to the subsurface. The diagram shows averaged nodal exchange fluxes (total nodal fluxes divided by an influence area of the node), plotted for visualization purposes as a continuous dataset.

a)

b)

Figure 6. (a) Normalized effective exchange fluxes for various peat soil geometries and hydraulic conductivity K_{peat}/K_{sand} ratios, in which K_{peat} varies between 1.0E-9 and 1.E-5 m/s. (b) Normalized effective exchange flux of overland zone for various peat soil layer geometries and slope ratios, in which i) slope of mineral slope varies between 0.75% and 5 and slope of peat zone is kept constant and ii) slope of peat zone varies between 0.3 and 2% and slope of mineral zone is kept constant.

Figure 7. Exchange fluxes for conceptual models (CMs) 5a-d differing in terms of vertical discretization (dy) plotted with reference to no peat CM 1a (no peat dy=10cm) and case study peat soil layer geometry representation CM 1d (case study dy=10 cm); all other settings in the models were the same as in the reference model. Positive groundwater-surface water (GW-SW) exchange flux values indicate locations of groundwater discharge to overland zone, negative values indicate areas where water infiltrates to the subsurface. The diagram shows averaged nodal exchange fluxes (total nodal fluxes divided by an influence area of the node), plotted for visualization purposes as a continuous dataset.
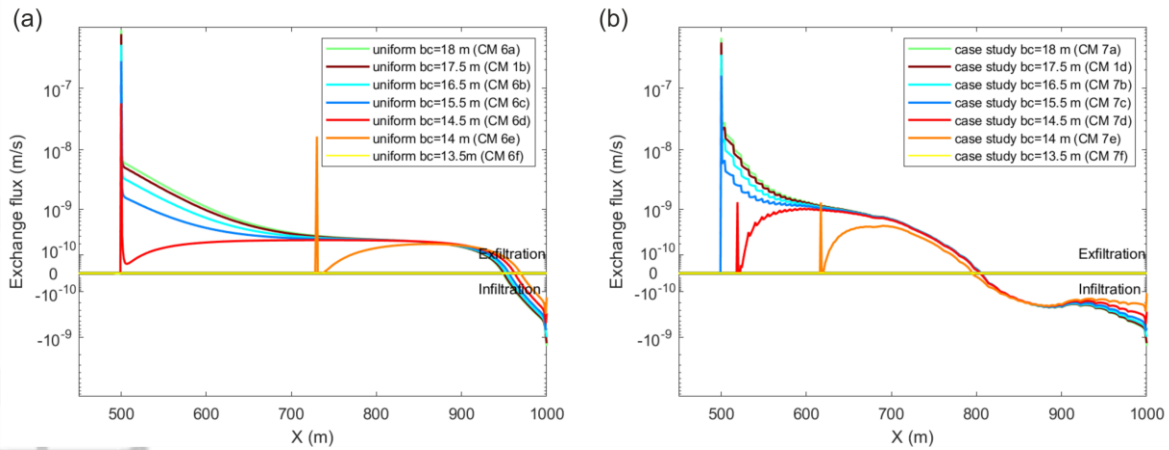

Figure 8. Exchange flux in the wetland area (x-axis 500-1000 m) for changing boundary conditions representing long-term pumping (bc=13.5-16.5 m) and wet conditions (18 m) in comparison with the reference model (bc=17.5 m) for (a) the uniform and (b) the case study peat soil layer geometry representations. Positive groundwater-surface water (GW-SW) exchange flux values indicate locations of groundwater discharge to overland zone, negative values indicate areas where water infiltrates to the subsurface. The diagrams show averaged nodal exchange fluxes (total nodal fluxes divided by an influence area of the node), plotted for visualization purposes as a continuous dataset.

Table 1. Peatland conceptualization in fully-integrated physically-based models. The studies are presented in chronological order and include non-peer-reviewed publications.

Study	Study objective	Software	Model dimen-sionality	Domain size	Mesh resolution	Peat thickness	Peat hydraulic properties
Smerdon et al. (2007)	Simulations of lake-groundwater interactions in Alberta's Boreal Plains region	Hydro-GeoSphere	3D	3.24 km²	Horizontal: 20 m; Vertical: 0.25 m in the top 1 m; variable thickness layers below	Uniform *	Same for the whole peat
Frei et al. (2010)	To improve understanding of the effects of micro-topography on surface-subsurface exchange and runoff generation in a riparian wetland	HydroGeo-Sphere	3D	200 m² (10 m x 20 m x 2 m)	Horizontal: 0.1 m; Vertical: 0.1 m	Uniform (2 m)	Same for the whole peat
Frei et al. (2012)	To investigate how subsurface flow patterns induced by surface micro-topography affect subsurface transport of redox-sensitive solutes and the distribution of biogeochemical processes	HydroGeo-Sphere	3D	200 m² (10 m x 20 m x 2 m)	Horizontal: 0.1 m; Vertical: 0.1 m	Uniform (2 m)	Same for the whole peat
Dureijka (2013)	To determine the overall water balance for a peatland influenced by lake level variations and how the exchange between peatland and the adjacent lake is characterized	HydroGeo-Sphere	3D	5.61 km²	Horizontal: unknown, highest discretization along drainage and observation points; Vertical: 0.1m in the top 1 m and the rest divided into 5 equally spaced layers	Uniform (6 m)	Variable with depth
Partington et al. (2013)	To understand and quantify streamflow generation processes at the catchment scale	HydroGeo-Sphere	3D	Riparian wetland (Frei 2010, 2012): 210 m²; catchment scale: 4.2 km²	Horizontal: varies between 10-100m; Vertical: 0.1 m in the top 1 m, variable thickness layers below	Uniform (1 m)	Hydraulic conductivity variable with depth; other values kept constant
Frei & Fleckenstein (2014)	To test whether surface microtopography can be sufficiently replicated by a planar model superimposed on spatially distributed rill/ depression storage height variations.	HydroGeo-Sphere	3D	200 m² (10 m x 20 m x 2 m)	Horizontal: 0.1 m; Vertical: 0.1 m	Uniform (2 m)	Same for the whole peat
Ala-aho et al. (2015a)	To study the temporal and spatial exchange between GW and lakes and streams	HydroGeo-Sphere	3D	250 km²	Horizontal; Vertical: 0.2 m, 0.5 m, 0.9 m, 1.4 m and two	Uniform (average peat depth of 1.4 m)	Same for the whole peat

					proportional layers		
Jaros (2015)	To examine the performance of fully-integrated modeling in simulating groundwater-dependent ecosystems	HydroGeo-Sphere	3D	92.9 km^2	Horizontal: 14-210 m; finer discretized around features of interest; average segment length 90 m; Vertical: 0.05 m, 0.1 m, 0.15 m, 0.25 m, 0.4 m, 0.65 m, 1.05 m, 1.8 m and the rest divided into two proportional layers	Uniform (1.8 m)	Same for the whole peat
Thompson et al. (2015)	To evaluate the hydrological linkages occurring between landscape units in a pond-peatland complex of Alberta's Boreal Plains region	HydroGeo-Sphere	2D	Transect 1: ~450 m; Transect 2: ~750m	Horizontal: 1 m; Vertical: 0.05 m to 0.1 m in the upper 0.5 m and 0.25 m below	Varying thickness; accuracy 0.25 m	All properties variable with depth
Haahti et al. (2016)	To examine the performance of fully-integrated models to simulate interactions between a drainage network and peatland moisture conditions	FLUSH	3D	0.052 km^2	Horizontal: 5 m x 5 m; Vertical: 8 x 0.05 m, 6 x 0.1 m and 4 x 0.25 m from top to bottom; in total 18 layers	Uniform (2 m)	Hydraulic conductivity and water retention curve parameters variable with depth
Haahti et al. (2016)	To understand erosion mechanisms after ditch network maintenance in forested peatlands	FLUSH	3D	0.052 km^2	Horizontal: 5 m x 5 m; Vertical: 8 x 0.05 m, 6 x 0.1 m and 4 x 0.25 m from top to bottom; in total 18 layers	Uniform (2 m)	Hydraulic conductivity and water retention curve parameters variable with depth
Ala-aho et al. (2017)	To investigate how the subsurface is involved in sustaining and generating streamflow in a glaciated headwater catchment; to define parameter sensitivities across all model domains; to determine what data are useful to include in model calibration	HydroGeo-Sphere	3D	3.3 km2	Horizontal: unknown; highest discretization along a stream with average segment lengths of 9.6 m; Vertical: 0.05 m in the top 0.2 m, 0.1 m at 0.2-1 m depth, 0.5 m at 1-2 m depth and rest divided into 5 equally spaced layers	Classified into three depth zones: 0.2 m, 1 m, 2 m	Same for the whole peat domain
Thompson et al. (2017)	To predict climate change impacts on ecosystems in a catchment of Alberta's Boreal Plains	HydroGeo-Sphere	2D	Transect 1: ~450 m; Transect 2: ~750m	Horizontal: 1m; Vertical: 0.05 to 0.1 in upper 0.5 m and 0.25 below	Variable; accuracy 0.25 m	All properties variable with depth
Haahti et al. (2018)	To evaluate sediment control scenarios practices used in	FLUSH	3D	0.052 km^2	Horizontal: 5 m x 5 m;	Uniform (2 m)	Hydraulic conductivity and water

					Vertical: 8 x 0.05 m, 6 x 0.1 m and 4 x 0.25 m from top to bottom; in total 18 layers		retention curve parameters variable with depth
Hwang et al. (2018)	To investigate why long-term annual downstream flow rates are consistently higher than upstream rates under the subhumid water deficit conditions in the Athabasca River Basin covered by peatlands and forestlands	HydroGeoS phere	3D	160,000 km^2	Horizontal: 3 km (refined to 0.5 km close to the main drainage features) Vertical: varying thickness; thickness of the first top layers less than 0.5 m, third layer 1.5 n and fourth layer 1 m; other layers depth unknown	Varying thickness represented by 4 layers of variable depth	Two layers of dual-porosity model: highly conductive layer in top 0.5 m and the less conductive layer below 0.5 m
Jaros et al. (2019)	To investigate the effect of parameterization with global sensitivity analysis on groundwater-surface water interactions in a boreal esker-aapa mire system	HydroGeo-Sphere	3D	107 km^2	Horizontal: unknown; Vertical: 0.05 m, 0.1 m, 0.25 m, variable depth of the interface between high K and low K layers, 1.35 m and rest divided into two proportional layers	Uniform (variable depth of the interface between high K and low K layers); bottom at 1.35 m	Two layers: highly conductive layer and less conductive layer

*Information not implicitly stated in the manuscript

Table 2. Summary of the conceptual models (CMs) investigated in this study. Modified conditions with respect to the reference model (1a) are reported for each case.

Property investigated	CM	Peat soil depth representation	Specified head boundary condition at the left edge (m)	Slope (mineral soil)	Slope (peatland)	Mineral soil type	Vertical discretization of top 4 m (m)	Hydraulic conductivity of peat (m/s)
1. Peat layer geometry	1a	No peat	17.5	3 %	0.50 %	Sand	0.1	1.00E-07
	1b	Uniform depth	-	-	-	-	-	-
